One of the difficulties in adiabatic quantum computation is the limit on the computation time. Here we propose two schemes to speed-up the adiabatic evolution. To apply this controlled adiabatic evolution to adiabatic quantum computation, we design one of the schemes without any prior knowledge of the instantaneous eigenstates of the final Hamiltonian. Whereas in another scheme, the control is constructed with the instantaneous eigenstate that is the target state of the control. As an illustration, we study a two-level system driven by a time-dependent magnetic field under the control. The physics behind the control scheme is explained.

PACS numbers: 03.65.-w, 03.65.Ta, 02.30.Yy

Adiabatic quantum computation (AQC) was first proposed in 2000[1] as a means to solve NP-complete problems. It is polynomially equivalent to conventional (gate model) quantum computation[2] and possesses some degree of fault tolerance. AQC can be described by the following Hamiltonian,

$$H_0(t) = [1 - \lambda(t)]H_i + \lambda(t)H_f, \quad (1)$$

where the quantum system govern by $H_0(t)$ evolves slowly with time t and remains in its ground state as $\lambda(t)$ changes monotonically from 0 to 1 within a time T . The initial Hamiltonian H_i is assumed to have an easily accessible ground state into which the system is initialized, while the ground state of the final Hamiltonian H_f encodes a problem's solution. In order to reach the final ground state with high fidelity, the adiabatic theorem requires $T \propto (\Delta E_{\min})^{-\delta}$, where $\Delta E_{\min}$ is the minimum gap between the two lowest energy eigenstates of $H_0(t)$. The power δ can be 1, 2, or possibly some other number depending on the functional form of $\lambda(t)$ and the distribution of the higher energy levels [1, 3, 4]. This leads to a limit on the computation time T , which holds true for adiabatic quantum computation *without quantum control*, thus it is natural to ask whether one can use quantum control to speed up AQC?

Quantum control[5, 6, 7, 8, 9, 10, 11, 12, 13, 14] is about the application of classical and modern control strategy to quantum systems. It has generated increasing interest in the last few years due to its potential applications in metrology[15, 16], communications[17, 18] and other technologies [19, 20, 21, 22, 23], as well as its theoretical interest on its own. Several approaches to the control of a quantum system have been proposed in the past decade, which can be divided into coherent (unitary) and incoherent (non-unitary) control, according to how the controls enter the dynamics. In the coherent control scheme, the controls enter the dynamics through the system Hamiltonian. It affects the time evolution of the system state, but not its spectrum, i.e., the eigenvalues of the target density matrix ρ_f remain

unchanged in the dynamics. In the incoherent control scheme, an auxiliary system, called probe, is introduced to manipulate the target system through their mutual interaction. This incoherent control scheme is of relevance whenever the system dynamics can not be directly accessed and provides a non-unitary evolution for the quantum system. This breaks the limitation for the coherent control mentioned above. Among these quantum control strategies, Lyapunov control plays an important role in quantum control theory. Lyapunov functions, originally used in control to analyze the stability of the control system, have formed the basis for new control design. Several papers have been published recently to discuss the application of Lyapunov control to quantum systems[24, 25, 26, 27, 28, 29, 30, 31]. Although the basic mathematical formalism for Lyapunov control is well established, many questions remain when one considers its applications in quantum information processing, for instance, whether one can use quantum Lyapunov control to improve the adiabatic evolution, and consequently minimize the computation time?

In this paper, we shall address this issue by using a two-level model with Lyapunov control. Since the two lowest levels are important for AQC, this model to some extent can good quantify the AQC under control. Two control schemes are proposed which correspond to two different choices of Lyapunov function. By numerical simulation, we find that these schemes work well. The paper is organized as follows. In Sec.II, we present a general formalism for the Lyapunov control, two Lyapunov functions which will give two control schemes are constructed, then we use these schemes to manipulate a two-level system in Sec.III. Conclusion and discussions are presented in Sec.IV.

General formalism.— Let us start by focusing on the Hamiltonian $H_0(t)$ in Eq.(1). We denote the instantaneous eigenstates and the corresponding eigenvalues of $H_0(t)$ by $|n(t)\rangle$ and $E_n(t)$, respectively. AQC is designed to take advantage of the adiabatic theorem, it works by evolving a system from the accessible ground state of an initial Hamiltonian H_i to the ground state of a final

Hamiltonian H_f . For the system to remain in its ground state, the adiabatic theorem requires that the system Hamiltonian changes very slowly and there is an energy gap between the ground state and the others. The goal of this paper is to manipulate the system such that it remains in one of its eigenstates. To meet the requirement of AQC, any information about the instantaneous eigenstates of H_f is forbidden to use in the control, but a prior knowledge regarding the system Hamiltonian is allowed. This motivates us to propose the first scheme in the following. Beside the interests in AQC, controlling a quantum system to a target state is interesting on its own. As the target state is known, the information about the target state can be used in the control design. This is the goal of the second scheme discussed in this paper.

Scheme A.— We aim to design a control scheme that can manipulate a system to remain in its instantaneous ground state without any prior knowledge of its instantaneous eigenstates of H_f . To this end, we introduce control operators H_{cj} ($j = 1, 2, 3, \dots$) and require that $[H_0, H_{cj}] = 0$ for any j . The control operators H_{cj} enter the system through control field $f_j(t)$. The total Hamiltonian of the system is then written,

$$H = H_0 + \sum_j f_j(t) H_{cj}, \quad (2)$$

where the control field $f_j(t)$ can be established by Lyapunov control theory. Define a function $V(t)$ as

$$V(t) = |\langle \psi(t) | X | \psi(t) \rangle|^2, \quad (3)$$

with X being a time-independent Hermitian operator, we find $V(t) \geq 0$ and

$$\dot{V}(t) = \frac{2i}{\hbar} \langle \psi(t) | X | \psi(t) \rangle \langle \psi(t) | [H, X] | \psi(t) \rangle. \quad (4)$$

Here and hereafter $|\psi(t)\rangle$ denotes the state of the system that satisfy $i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle = H |\psi(t)\rangle$. We now show how to establish the control field $f_j(t)$. Lyapunov control theory tells that for $V(t)$ to be a Lyapunov function, $V(t)$ has to satisfy, $V \geq 0$ and $\dot{V} \leq 0$. So, if we choose the control field $f_j(t)$ as

$$\begin{aligned} f_j(t) &= i \langle \psi(t) | X | \psi(t) \rangle \langle \psi(t) | [H_{cj}, X] | \psi(t) \rangle, \quad \text{for } j \neq j_0, \\ f_{j_0}(t) &= -\frac{\langle \psi(t) | [H_0, X] | \psi(t) \rangle}{\langle \psi(t) | [H_{cj_0}, X] | \psi(t) \rangle}, \quad \text{for } j = j_0, \end{aligned} \quad (5)$$

then $\dot{V} \leq 0$. Here j_0 was specified to satisfy $\langle \psi | [H_{cj_0}, X] | \psi \rangle \neq 0$. Clearly $f_j(t)$ is a time-dependent real number, thus the total Hamiltonian H is Hermitian. The key point of this control scheme is the choice of operator X , it dominates the success rate of the control and show the merit in this scheme. From the control design of the scheme, we find that the instantaneous eigenstates do not enter the control, this mean that by the present

control strategy, we can manipulate the quantum system to evolve along one of the eigenstates without any knowledge of its instantaneous eigenstates. This is exactly what we want in AQC. To see that this control scheme indeed works, we note that $[H_0, H_{cj}] = 0$, indicating the control H_{cj} itself can not induce population transfer among the instantaneous eigenstates. Suppose that the system is initially prepared in its ground state $|0(t=0)\rangle$ and $H_{cj} = H_0$, Eq.(5) yields $f_{j_0}(t=0) = -1$ and $f_j(t=0) = 0$, ($j = 1, 2, 3, \dots, j \neq j_0$), regardless of what X takes. When $|\psi(t)\rangle$ deviates from $|0(t)\rangle$, $f_j(t)$ can be very large depending on operator X . The Lyapunov control will then render the system nonlinear, and this nonlinear effect would bring the state $|\psi(t)\rangle$ back to $|0(t)\rangle$. We note that $\frac{\partial H_{cj}}{\partial t}$ (as well as $\frac{\partial H_0}{\partial t}$) can derive the system from one instantaneous eigenstate to the others, this together with the control keep the system in the instantaneous eigenstate into which the system was initially prepared. We will demonstrate this point through an example in detail later.

Scheme B.—For general control problem, the target state is known, we then can use the target state to design a Lyapunov function and establish the control field $f_j(t)$. Suppose that the target state is the zeroth instantaneous eigenstate $|0(t)\rangle$ of $H_0(t)$, define

$$V(|0(t)\rangle, |\psi(t)\rangle) = 1 - |\langle 0(t) | \psi(t) \rangle|^2. \quad (6)$$

Clearly $V \geq 0$ with equality only if $|0(t)\rangle = |\psi(t)\rangle$. To see Eq.(6) indeed defines a Lyapunov function, we calculate the time derivative of V as ($H = H_0 + \sum_j f_j(t) H'_{cj}$ in this scheme),

$$\begin{aligned} \dot{V} &= -\frac{i}{\hbar} \sum_j f_j(t) (\langle \psi(t) | H'_{cj} | 0(t) \rangle \langle 0(t) | \psi(t) \rangle - c.c.) \\ &\quad - 2\text{Re}(\langle \dot{0}(t) | \psi(t) \rangle \langle \psi(t) | 0(t) \rangle). \end{aligned} \quad (7)$$

Obviously,

$$\begin{aligned} f_j(t) &= -2\text{Im}(\langle \psi(t) | H'_{cj} | 0(t) \rangle \langle 0(t) | \psi(t) \rangle), \quad \text{for } j \neq j_0, \\ f_{j_0}(t) &= -\frac{\hbar \text{Re}(\langle \dot{0}(t) | \psi(t) \rangle \langle \psi(t) | 0(t) \rangle)}{\text{Im}(\langle 0(t) | H'_{cj_0} | \psi(t) \rangle \langle \psi(t) | 0(t) \rangle)}, \quad \text{for } j = j_0, \end{aligned} \quad (8)$$

guarantee that $\dot{V} \leq 0$. Again, j_0 was selected to satisfy $\text{Im}(\langle 0(t) | H'_{cj_0} | \psi(t) \rangle \langle \psi(t) | 0(t) \rangle) \neq 0$. Hence, the evolution of the system with Lyapunov control can be described by the following nonlinear autonomous equations,

$$\begin{aligned} i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle &= H |\psi(t)\rangle, \\ H &= H_0 + \sum_j f_j(t) H'_{cj}, \\ H_0 |0(t)\rangle &= E_0 |0(t)\rangle, \end{aligned} \quad (9)$$

where $f_j(t)$ ($j = 1, 2, 3, \dots$) are given by Eq.(8). Note that $[H'_{cj}, H_0] = 0$ is not required in this scheme. The

difference between the present scheme and those in the literature[30] is the target state. In earlier studies, the target state $|\phi_d\rangle$ is either time-independent or time-dependent via $i\hbar\frac{\partial}{\partial t}|\phi_d\rangle = H_0|\phi_d\rangle$, whereas in our scheme, the target state is one of the instantaneous eigenstate of H_0 . The time derivative of the instantaneous eigenstate plays an important role in the control, leading to totally different control fields $f_j(t)$ in Eq.(8). Note that the choice of $f_j(t)$ in Eqs.(5) and (8) are not unique. In fact, when there is only one control operator H_c , the control field $f(t)$ in Eq.(5) can be chosen as,

$$f(t) = i\langle\psi(t)|X|\psi(t)\rangle\langle\psi(t)|[H_c, X]|\psi(t)\rangle - \frac{\langle\psi(t)|[H_0, X]|\psi(t)\rangle}{\langle\psi(t)|[H_c, X]|\psi(t)\rangle}, \quad (10)$$

provided $f(t)$ is a finite number. This is exactly the case in the example that we will illustrate below.

Example.— As an illustration of the Lyapunov control scheme, we discuss below a two-level system driven by a time-dependent magnetic field. The Hamiltonian that describes such a system can be written as

$$H_0(t) = \mu\vec{B} \cdot \vec{\sigma} \quad (11) \\ = \mu B_0(\sin\theta \cos\phi\sigma_x + \sin\theta \sin\phi\sigma_y + \cos\theta\sigma_z),$$

where σ_x, σ_y and σ_z are the Pauli matrices, B_0 is the amplitude of the classical field. θ is specified to be a constant here, while ϕ depends on time t through $\phi = \omega t$ (ω , constant). In comparison with Eq.(1), H_i takes $\mu B_0(\sin\theta\sigma_x + \cos\theta\sigma_z)$, while $H_f = \mu B_0(\sin\theta\sigma_y + \cos\theta\sigma_z)$. Although in this model we can not found an analytical $\lambda(t)$ by which we write Eq.(11) in the form of Eq.(1), the model Eq.(11) can be obviously mapped into Eq.(1). It is well know that the instantaneous eigenstates and the corresponding eigenvalues of H_0 are $|E_+(t)\rangle = \cos\frac{\theta}{2}e^{i\phi}|\uparrow\rangle + \sin\frac{\theta}{2}|\downarrow\rangle$, $|E_-(t)\rangle = -\sin\frac{\theta}{2}e^{i\phi}|\uparrow\rangle + \cos\frac{\theta}{2}|\downarrow\rangle$ and $E_{\pm} = \pm\mu B_0$, respectively. In the absence of Lyapunov control, it is required that $\omega \ll \mu B_0$ for the system to evolve adiabatically. We now show that the system can evolve along one of its instantaneous eigenstates, e.g. $|E_-(t)\rangle$, under the Lyapunov control even if $\omega \geq \mu B_0$. In the following, a fidelity defined by

$$F(t) = |\langle E_-(t)|\psi(t)\rangle|^2, \quad (12)$$

will be used to measure the effectiveness of the control. The dependence of $F(t)$ on time t and the control operator H'_c as well as X are shown. The results show that these schemes work good with properly chosen X and H'_c .

We first consider the scheme A, where no information about instantaneous eigenstates enter the control. Choose $X = \sigma_x + R\sigma_z$ with a rate R , the dynamics of the two-level system under control is governed by

$$i\hbar\frac{\partial}{\partial t}|\psi(t)\rangle = H|\psi(t)\rangle,$$

FIG. 1: (Color online) Fidelity defined by $F(t) = |\langle E_-(t)|\psi(t)\rangle|^2$ as a function of time. The system is initially prepared in $|E_-(t=0)\rangle$. (a)-(e) correspond to different rate R . From (a) to (e), $R = 12, 9, 6, 3, 0$, respectively. By contrast, the result without control is shown by the dashed line. We have set $\mu B_0 = 1$ for this plot. The time is shown in units of $1/(\mu B_0)$, the other parameters chosen are $\omega = 4$ (in units of μB_0) and $\theta = \frac{\pi}{4}$. Note $\omega = 4\mu B_0$, the adiabaticity breaks for the system without control.

$$H = \mu\vec{B} \cdot \vec{\sigma} + f(t)H_c, \quad (13) \\ f(t) = i\langle\psi(t)|X|\psi(t)\rangle\langle\psi(t)|[H_c, X]|\psi(t)\rangle - \mu B_0.$$

Here H_c was specified to be $H_c = (\sin\theta \cos\phi\sigma_x + \sin\theta \sin\phi\sigma_y + \cos\theta\sigma_z)$ in order to satisfy $[H_c, H_0] = 0$. We have performed extensive numerical simulations for the dynamics Eq.(13), selected results are plotted in Fig. 1. Two observations can be found from Fig.1. (1) The scheme works only for special X . For some choices of X , the control favors the adiabatic evolution, but for the other X , the control spoils the adiabaticity of the evolution. (2) For the specified X , $X = \sigma_x + R\sigma_z$, the larger the ratio R is, the better the fidelity for the system in $|E_-(t)\rangle$.

In the scheme B, a prior knowledge of the instantaneous eigenstates is known and allowed to use to design the control field $f(t)$. Choose $|E_-(t)\rangle$ as the target state, the dynamics of the system is governed by Eq.(9) with replacing $|0(t)\rangle$ by $|E_-(t)\rangle$. We show in Fig.2 the fidelity as a function of time with $H'_c = \sigma_z + r\sigma_x$. Similar to the results given in the scheme A, the choice of the control operator H'_c dominates the effectiveness of the control. Not all control operator H'_c can help the adiabatic evolution. The difference between these two schemes is that the scheme B can reach fidelity 1 at the final stage, this may depend on the example demonstrated.

For linear quantum system, the population transfer from one instantaneous eigenstate to the others depends on the energy gap and the operator that induces the transfer. The energy gap separates the instantaneous eigenstates and ensures the adiabaticity of the evolution. The larger the energy gap is, the higher the probability with which the system remains in the instantaneous

FIG. 2: (Color online) Fidelity versus time t given by the scheme B. The fidelity was defined as the same as in Fig.1. From (a) to (e), the ratio r takes 0, 2, 4, 6, 8, respectively. Dashed line shows the result without control. All quantities are chosen and plotted in the same units as in Fig.1.

FIG. 3: (Color online) Eigenvalues of Hamiltonian H as a function of time. The parameters chosen are the same as in Fig.1-(a), indicating that the system remains well in one of the instantaneous eigenstates under control. The inset shows an enlarged level anti-crossing point.

eigenstate. In the scheme A, the operator that induces the population transfer is $\delta H = (\frac{\partial H_0}{\partial t} + f(t)\frac{\partial H_c}{\partial t})$, small δH would benefit the adiabaticity of the system. For nonlinear system, however, the nonlinearity plays an important role in addition to the factors for linear system mentioned above. All these factors together lead to the observed features and can be used to understand the physics behind the features.

To make the explanation clear, we plot the eigenvalues for the total Hamiltonian in scheme A as a function of time in Fig.3. The same parameters as in Fig.1-(a) are chosen, which ensure that the state of the system remains in the instantaneous eigenstate $|E_-(t)\rangle$. Recall that the energy gap between two instantaneous eigenstates is 2 (in units of μB_0) for H_0 , we find from Fig.3 that the energy gap is intensively enlarged at most times by the control. Nevertheless, the enlarged energy gap itself can not explain why the system remains well in the instantaneous eigenstate, because the energy gap is

very small at the level anti-crossing points, this indicates that the nonlinearity must play an important role in the dynamics. Indeed our numerical calculation shows that at these point, the nonlinear coefficient defined by $|\langle E_-(t) | f(t) H_c | E_-(t) \rangle|$ is much larger than the tunneling coefficient $|\langle E_-(t) | \delta H | E_+(t) \rangle|$, leading to the observed feature reminiscent of self-trapping in nonlinear system.

To sum up, we have proposed two schemes to speed-up the adiabatic evolution. In the scheme A, the control has been designed without any information about the instantaneous eigenstates of the final Hamiltonian, hence this scheme can be used in the adiabatic quantum computation. The scheme B has been proposed using the instantaneous eigenstate of the system Hamiltonian. This scheme is applicable to control a quantum system when the target state is known. To show how the schemes work, we have presented an example consisting of a two-level system in a rotating magnetic field. The fidelity to quantify the effectiveness of the scheme was calculated and discussed. The results show that the fidelity depends sharply on the choice of X and the control operator H_c' . The physics behind the schemes is revealed, which can be understood as an effect combining nonlinear effects and the broadened energy gap.
